FORMATION OF IRON CARBONYL BETWEEN A 1/2% Mo STEEL AND HIGH-PRESSURE GASES CONTAINING CARBON MONOXIDE

H. Inouye and J. H. DeVan

ABSTRACT

An atomic absorption spectrophotometer was used to measure the formation of iron carbonyl between 1/2% Mo steel pipes and flowing high-pressure gases (to 6.9 MPa) containing carbon monoxide. The net formation rate, $\dot{F}$, of iron carbonyl was measured as a function of the velocity, temperature, and pressure of the gases to determine the conditions that prevent its formation. These variables and the gas composition affected $\dot{F}$ as follows: (1) Rate $\dot{F}$ increases linearly with the gas velocity. Under equilibrium conditions, $\dot{F}$ is proportional to the gas velocity, but it reaches a limiting value above a critical gas velocity when equilibrium is not maintained. (2) Between 44 and 266°C, $\dot{F}$ increases with temperature to a sharp maximum at 177°C in a gas mixture containing 17 CO-51 H2-30 CH4-2 CO2 (vol %). The corresponding maximum in carbon monoxide occurs at 245°C. The data predict that iron carbonyl formation will be negligible above 270°C in the gas mixture or above 285°C in carbon monoxide. (3) Rate $\dot{F}$ depends on $P_{CO}$ in accordance with the equation $\dot{F} = k_{CO} P_{CO}^n$, where $n = 4$ to 5 under equilibrium conditions and $n = 2$ off equilibrium. The analytical procedure used to detect ±6 vpb (volume parts per billion) of iron carbonyl and ±1.5 vpb of nickel carbonyl in flowing high pressure gases is described. The reaction rates are described in terms of kinetics and thermodynamic equilibrium.

INTRODUCTION

The production of synthetic natural gas (SNG) from coal involves reacting hydrogen and carbon monoxide over a Raney nickel catalyst to produce methane. Deposition of iron on the methanation catalyst converts it to a Fisher-Tropsch catalyst, and this is thought to be one of the reasons for the decrease in the methane yield during the lifetime of the catalyst. Iron pentacarbonyl formed by the reaction of carbon monoxide with the steel piping leading to the methanation reactor is
believed to be the source of the iron. Therefore, this study was
directed toward finding practical methods of preventing carbonyl
formation in structural steels, initially through a systematic evaluation
of various steels, then by a study of preventive techniques such as
coatings. This report summarizes the variables governing the formation
of iron carbonyl resulting from the reaction of 1/2% Mo steel (A 334-P1)
with a flowing gas mixture containing 17 CO–51 H₂–30 CH₄–2 CO₂ and with
100 CO (vol %) between 44 and 266°C and gas pressures to 6.98 MPa
(1000 psi). Iron and nickel carbonyl formation between type 316 stain-
less steel and the above gases was also briefly investigated.

PREVIEW WORK

A literature survey of the thermodynamic and kinetic data for
iron and nickel carbonyl formation was completed before we started
this study. The principal conclusions of this survey are summarized
below. At moderate temperatures (100–250°C) and pressures (0.1–101 MPa)
the attack upon steel pipes by carbon monoxide is limited by the reaction
rate. In static carbon monoxide the formation rate, $r$, of iron carbonyl
from iron powder or millings reached a maximum at 200°C for carbon
monoxide pressures between 10 and 100 MPa. An analysis of data from
Ref. 5 showed that $r$ increased significantly with the gas velocity;
however, the effect of temperature on carbonyl formation in flowing
gases was not determined.

Stoffel determined that $r$ depended on $P_\text{CO}^{2.6}$, whereas the data of
Mond and Wallis gave a pressure dependence of $P_\text{CO}^{1.67}$. A pair of data
points in Ref. 5 indicate that $r$ depends on $P_\text{CO}^{1.76}$. Table 1 (based on
Ref. 5) is a summary of the corrosion of steels of interest in carbon
monoxide and in a gas mixture containing 30 CO–60 H₂–10 N₂ (vol %) at
101 MPa (1000 atm). Although a direct comparison of the data in each
test gas cannot be made (because the dependence of $r$ on $P_\text{CO}$ in the gas
mixture is unknown), the data show increasing resistance to carbon
monoxide attack as the chromium and nickel contents in the steel
increase. In contrast, an increase in the carbon content of iron
from 0.1 to 2.9% (cast iron) increases the corrosion rate by a factor

of 35% The cast iron rod was reduced to a skeleton of "phosphide eutectic of cast iron with a narrow residue of ferrite" having the same initial dimensions. In the case of all steels, any measurable amount of corrosion by carbon monoxide was accompanied by a net increase in the carbon content due to the deposition of free carbon on the surface. Data from Ref. 5 further show that the corrosion rate of the 1/2% Mo-0.15% C steel can be expected to be significantly greater in the CO-H₂-N₂ mixture than in carbon monoxide (see Table 1).

**EXPERIMENTAL PROCEDURE**

**Autoclave System**

Figure 1 is the schematic arrangement of the type 316 stainless steel system used to measure the formation rate of iron carbonyl. The two autoclaves placed in series are each 159 mm OD by 16 mm wall by
Fig. 1. The Autoclave System and the Atomic Absorption Spectrophotometer Arranged as Shown was Used to Measure $6 \text{ vpb}$ and $12 \text{ vpb}$ of Iron and Nickel Carbonyls, Respectively, in Flowing Gases to 6.9 MPa (1000 psi).

705 mm long. The test gas from gas cylinders flows continuously through a bed of activated charcoal at room temperature in the first autoclave to remove any metal carbonyls that might be present. Steel specimens are heated to the reaction temperature in the second autoclave and are then allowed to react with the gas leaving the charcoal trap. The effluent gas from the reaction vessel is cooled and depressurized to normal temperature and pressure ($20^\circ\text{C}$ and 0.1 MPa) and analyzed for its carbonyl content with an atomic absorption spectrophotometer (AAS).

Pressure regulators on the gas cylinders and a Heise high-precision absolute pressure gage were used to control gas pressures to $\pm 69 \text{ kPa}$ during a run. The flow rates were adjusted as desired by regulating the rate at which the effluent gases were vented to the exhaust system. The test gases were supplied in steel tanks at 10.3 MPa and were used without further treatment except as noted above. The vendors' analyses of the gas mixture, which were within 2% of the nominal, were assumed to be
correct. The gas entering the reaction vessel was preheated to within 5°C of the autoclave temperature with heater tapes around the feed lines. A three-zone furnace around the specimen autoclave was used to hold its temperature to within ±1°C along its 700-mm length.

Test Procedure

The 1/2% Mo steel specimen consisted of four lengths of pipe each 33.3 mm OD by 4.75 mm wall thickness by 600 mm long and coated on the outside with water glass (Na₂SiO₃) to exclude contact with the test gases. The specimen surface area exposed to the gases was calculated to be 1795 cm². Forty-eight aluminum rods, also 600 mm long, filled the bore of the pipes and the spaces between the pipes and the autoclave wall to reduce the void volume and area (2881 cm³ and 42.43 cm²), to increase the heat capacity of the autoclave, and to reduce the temperature gradient.

In a typical run, the steel pipes are pretreated in 1.03 MPa (150 psi) static hydrogen for at least 16 hr at 150°C or at the test temperature if over 150°C. After the system is vented and hydrogen is purged with the flowing test gas, the system is pressurized and the AAS is placed in operation. The carbonyl concentration in the effluent test gases is continuously measured until a constant value is reached for each gas flow. Experimentally, this point was reached after 1.5 complete volume changes in the autoclave gases. The net formation rate of iron carbonyl is computed as the product of the volume fraction of iron carbonyl, as determined by the AAS, and the volume flow rate of the effluent gas at normal temperature and pressure (NTP). At the conclusion of a run, the system is depressurized, and the steel pipes are reconditioned in hydrogen before the next run.

Calibration of the AAS

Brief's technique with minor modifications was used to calibrate the AAS. In this technique the iron or nickel carbonyl in a 50-liter sample of a reference gas is absorbed in an appropriate solution, then
complexed to form a colored solution. The optical density of the complexed metal in the solution is measured with the AAS in terms of absorption units and compared with standard solutions containing known levels of iron or nickel. The calibrated reference gas is then used as the standard to determine the carbonyl concentration in the effluent gas from the autoclave. The uncertainty in the output of the AAS was about ±5 absorbance units, and a sensitivity of 1.3 vpb per absorbance unit for iron carbonyl gives an analytical capability of detecting ±6 vpb. For nickel carbonyl the sensitivity was 0.3 vpb per absorbance unit or a capability of detecting ±1.5 vpb.

RESULTS

Flow Rate Effects

Typically the iron carbonyl concentration in the effluent gas from the specimen autoclave decreased uniformly with the gas velocity* as shown in Fig. 2. The product of the iron carbonyl concentration (expressed as vpb) and the gas flow rate (liters/min at NTP) is the formation rate of iron carbonyl in units of nanoliters (at NTP) per minute. The specific formation rate, \( \dot{r} \), is defined as the rate of iron carbonyl formation per square centimeter of reacting surface and is determined by dividing the formation rate (nl at NTP/min) by the specimen surface (1795 cm\(^2\)). For convenience, figures showing reaction rates also give the equivalent grams of iron removed per square foot per year. The specific formation rate, \( \dot{r} \), increases with the gas velocity up to a critical velocity and remains constant at higher velocities (Fig. 3). The ranges of values for \( \dot{r} \) above the critical velocity, \( V_c \), for various temperatures and pressures are summarized in Table 2. On the average, \( V_c \) is 10.2 cm/min in the mixed gases and increases to 27.8 cm/min in carbon monoxide and is independent of temperature, pressure, and \( \dot{r} \). In the higher temperature

\*Gas velocity (cm/min) = flow rate at the test conditions (cm\(^3\)/min) ÷ 42.43 cm\(^2\) (void cross section of autoclave).
runs the iron carbonyl concentration was independent of the gas velocity [Fig. 4(a)]. Under these conditions $p$ is calculated to increase linearly with the gas velocity as shown in Fig. 4(b). This behavior was observed in runs 4, 20, 25, and possibly 3 and 17 in Table 2.

**In Carbon Monoxide**

Av. = 27.8

$^a$ Gas velocity above which $\dot{r}$ is independent of flow rate.

$^b$ At 20°C and 0.101 MPa (1 atm).

$^c$ Questionable.

$^d$ For a gas velocity = $V_{c}$ (av.).
Temperature Effects

For the mixed gases a bell-shaped curve is obtained when \( \dot{r} \) is plotted against temperature (Fig. 5). This curve, which is slightly skewed to the right, shows that \( \dot{r} \) increases with temperature to a maximum at 177°C, then decreases sharply above this temperature to a very low value at 266°C. A similar plot is obtained for carbon monoxide; however, \( \dot{r} \) reaches the maximum at about 246°C and falls off more rapidly with temperature than in the mixed gases. The formation rate of iron carbonyl for each gas at a \( P_{CO} \) of 1.17 MPa (170 psi) are compared in Fig. 6 to illustrate the large effect of the gas composition.

![Graph showing iron carbonyl formation rate vs. temperature](image)

Fig. 5. Iron Carbonyl Formation is Governed by the Surface Reaction Rate Below 177°C and by Equilibrium Above This Temperature. The bell-shaped curve is a result of these competing processes. Data are for the mixed gases at 6.9 MPa flowing at 10.2 cm/min.
Fig. 6. Iron Carbonyl Formation Between 1/2% Mo Steel and Carbon Monoxide is Promoted or Retarded by H₂, CH₄, and/or CO₂, Depending on the Reaction Temperature. Comparison is for P_{CO} = 1.17 MPa (170 psi).

Pressure Effects

The dependence of \( \dot{\rho} \) on the pressure of the mixed gases was determined from several separate runs (3, 4, 16, 17, 21, and 22 in Table 2), and the results are plotted in Fig. 7. The value of \( \dot{\rho} \) is proportional to \( P^{3.8} \) at 177°C and to \( P^{5.6} \) at 200°C. In CO, \( \dot{\rho} \) varied as \( P^{2.0}_{CO} \) at or below 200°C and varied as \( P^{2.3}_{CO} \) at 240°C (Fig. 8).

Effect of Test Gases on 1/2% Mo Steel

After the tests described above were completed, the steel pipes still had an adherent coating of Na₂SiO₃ on the external surfaces; however, the internal surfaces were covered with a black loose deposit assumed to be carbon. Analyses of turnings 0.51 mm thick from the inside surface of the pipes showed that the original carbon content of 0.05 wt % had increased to 0.30 wt % after testing in the gases.
Fig. 7. The Formation Rate, $\dot{r}$, of Iron Carbonyl Between 1/2% Mo Steel and Mixed Gases Depends on the Pressure: $\dot{r} \propto P^n$. At 177°C, $n = 3.8$, and it increases to $n = 5.0$ at 200°C.

Fig. 8. The Formation Rate of Iron Carbonyl Between 1/2% Mo Steel and Carbon Monoxide Depends on the Pressure: $\dot{r} \propto P^n$, where $n \approx 2$ But Increases Slightly with Temperature.
Carbonyl Formation from Type 316 Stainless Steel

The reactions between type 316 stainless steel and the test gases were studied to determine whether the autoclave system was itself a source of carbonyls. No iron carbonyl was detected with either the mixed gases or carbon monoxide at temperatures to 300°C; however, at 200°C nickel carbonyl was measured in the effluent gases at concentrations just above the detection limit as shown in Fig. 9. The formation rate of nickel carbonyl between type 316 stainless steel and the mixed gases at 6.9 MPa is about 10 pl/cm² min (0.04 g/ft² year) at 200°C and decreases to about 7 pl/cm² min at 155°C.

Fig. 9. Nickel Carbonyl Near the Detection Limit of the AAS Forms Between Type 316 Stainless Steel Autoclave and 6.9 MPa Mixed Gases. No iron carbonyl forms at 200°C.

DISCUSSION

The present results confirm that the formation rate, \( \dot{r} \), of iron carbonyl between steels are carbon monoxide depends strongly on the gas flow rate, pressure, temperature, and steel composition; however,
this study further shows that the specific effects of these variables are significantly altered by the gases associated with the carbon monoxide, as discussed below.

Two distinct responses of \( \dot{\varphi} \) to the gas velocity are observed, depending on the temperature. At the lower temperatures \( \dot{\varphi} \) increases to a limiting value (Fig. 3), then becomes independent of the gas velocity. This suggests that \( \dot{\varphi} \) is diffusion limited up to a critical velocity, then becomes limited by a surface reaction. These critical velocities, \( V_c \), in the mixed gases and in carbon monoxide were on the average 10.2 and 27.9 cm/min (Table 2), respectively, and were evident only in those tests run at the lower temperatures. That these velocities are in the same ratios as the molecular weights of the test gases (i.e., 11.9 and 28.0 g/mol) suggests that \( V_c \) is determined by the interdiffusion coefficients of carbon monoxide or the iron carbonyl in each gas. At the higher temperatures \( \dot{\varphi} \) increases continuously with the gas velocity and exhibits no tendency to stabilize at a fixed formation rate (Fig. 4). This characteristic appears to be associated with the carbonyl reaction reaching equilibrium, as discussed in the following text.

The increase in \( \dot{\varphi} \) with temperature is attributed to an increase in the rate of carbonyl reaction, and the sharp decrease in \( \dot{\varphi} \) with temperature at the higher temperature suggests that the reaction is approaching equilibrium. The competing processes result in the curves shown in Fig. 6. In Fig. 10, logarithms of iron carbonyl pressures attained in our tests with the 1/2% Mo steel in carbon monoxide at 1.17 MPa are plotted against \( 1/T \) and are compared with the equilibrium iron carbonyl pressures calculated from published\(^8-10\) equilibrium constants for the reaction of pure iron with carbon monoxide. At the higher temperatures our data give \( P_{Fe(CO)_5} \) values one to three orders of magnitude greater than the values based on published equilibrium data; however, the temperature dependence is almost the same as that predicted by Syrkin\(^8\) or Brief.\(^9\) The falloff of our iron carbonyl pressures from the log \( P_{Fe(CO)_5} \) versus \( 1/T \) relationship at the lower temperatures suggests that the pressures are limited by the surface reaction rate. The equilibrium constant for the formation of iron carbonyl between
Fig. 10. In Equilibrium with 1.17 MPa Carbon Monoxide, $P_{Fe(CO)\textsubscript{5}}$ is One to Three Orders of Magnitude Greater Than Published Data. Falloff from log $P_{Fe(CO)\textsubscript{5}}$ versus $1/T$ relationship below about 250°C is due to nonequilibrium conditions. 1 atm = 0.10 MPa.

the 1/2% Mo steel and carbon monoxide above 245°C, based on our test data and assuming that the reaction is Fe + 5CO $\rightarrow$ Fe(CO)$_5$, is calculated to be

$$\log K = \frac{9681}{T} - 28.188 ,$$  \hspace{1cm} (1)

in terms of pressures expressed in atmospheres. Similar calculations for iron carbonyl formation between the steel and the carbon monoxide in the mixed gases above about 177°C resulted in an expression significantly different from Eq. (1) even in terms of its temperature dependence. This suggests that the carbonyl formation reaction in the mixed gases involves a different chemical sequence than in pure carbon monoxide.
Figures 7 and 8 show that \( \dot{\rho} \) depends very strongly on the gas pressure and can be expressed by an equation of the form

\[
\dot{\rho} = kP^n,
\]

where

\( \dot{\rho} \) = formation rate of Fe(CO)\textsubscript{5},
\( k \) = constant, and
\( P \) = partial pressure of CO.

Our results for tests in carbon monoxide show that \( n \) is not constant but increases with temperature between 98 and 240°C (i.e., from 1.96 to 2.30); however, these values are in general accord with a pressure dependency of approximately \( P_{\text{CO}}^{2.0} \) as found by Stoffel.\textsuperscript{6} As noted earlier, \( n \) also increases with temperature in the mixed gases, the pressure dependence being 3.8 at 177°C and 5.0 at 200°C.

If the equilibrium reaction for iron carbonyl formation is

\[
\text{Fe} + 5\text{CO} \rightleftharpoons \text{Fe(CO)}_5,
\]

then the equilibrium constant is

\[
K = \frac{P_{\text{Fe(CO)}_5}}{P_{\text{CO}}^5}.
\]

Thus, under conditions where the reaction rate to form iron carbonyl is sufficiently fast for the specimen surface to approach equilibrium with the gas before it leaves the reaction vessel, the limiting pressure of iron carbonyl, \( [P_{\text{Fe(CO)}_5}]_{\text{eq}} \), is given by the product \( K(P_{\text{CO}})^5 \). Since

\[
\dot{\rho} = \left( \frac{P_{\text{Fe(CO)}_5}}{P_{\text{Total}}} \right) \cdot \text{Flow Rate},
\]

then

\[
\dot{\rho}_{\text{max}} = \left( \frac{KP_{\text{CO}}^5}{(1/k)P_{\text{CO}}} \right) \cdot \text{Flow Rate},
\]
or

\[ \dot{r}_{\text{max}} = KX(P_{\text{CO}})^n \cdot \text{Flow Rate}, \]  

(7)

where

\[ X = \text{mol fraction of CO}. \]

Under these limiting conditions, \( \dot{r} \) should vary with the fourth power of the carbon monoxide pressure (at a given flow rate), or when \( n = 4 \), the iron carbonyl concentration is presumably approaching the equilibrium value.

On the other hand, the net reaction between iron and carbon monoxide must result in the formation of both iron carbonyl and free carbon as experimentally observed. Since Fe₃C is formed during the deposition of carbon,^{11} a possible chemical sequence satisfying the observations might be as follows:

\[
\begin{align*}
3 \text{Fe} + 2 \text{CO} & \rightleftharpoons \text{Fe₃C} + \text{CO}_2,
\end{align*}
\]

(8)

\[
\begin{align*}
\text{Fe₃C} + 15 \text{CO} & \rightleftharpoons 3 \text{Fe(CO)}_5 + \text{C} ,
\end{align*}
\]

(9)

which when added give

\[
3 \text{Fe} + 17 \text{CO} \rightleftharpoons 3 \text{Fe(CO)}_5 + \text{C} + \text{CO}_2 .
\]

(10)

Recalculation of the pressure dependence of iron carbonyl formation on \( P_{\text{CO}} \) in the manner described in Eqs. (5) through (7) and assuming that the reaction proceeds as in Eq. (10) gives \( n = 4.7 \) as the upper limit; that is, \( \dot{r} \) should theoretically vary as the 4.7 power of the \( P_{\text{CO}} \) under conditions approaching equilibrium.

The reaction sequence given by Eqs. (8) and (9) is reasonably consistent with our test results for the mixed gases. In Fig. 6 we assumed that \( \dot{r} \) at temperatures above the maxima is governed by thermodynamic equilibrium. This conclusion is corroborated by our prediction that \( \dot{r} = kP_{\text{CO}}^{4.7} \), compared with a measured value of \( \dot{r} = kP_{\text{CO}}^{5.0} \) in the mixed gases under conditions approaching equilibrium. Since our measurements
of the pressure dependence of $r$ in CO were in the temperature range assumed to be governed by the surface reaction rate, values of $n < 4.7$ (e.g., $n = 2.0$ to 2.3) should be expected.

SUMMARY AND CONCLUSIONS

A 1/2% Mo steel was exposed to high-pressure carbon monoxide and to a gas mixture containing 17 CO–51 H$_2$–30 CH$_4$–2 CO$_2$ (vol %) to measure the rate of formation of iron carbonyl in steel piping leading to a methanation reactor. The variables affecting the formation rate, $r$, were confirmed to be the gas velocity, temperature, and pressure. This study also shows that the presence of H$_2$, CH$_4$, and/or CO$_2$ in CO can significantly promote or retard the reaction of steel with CO, depending on the test conditions:

1. Rate $r$ increases linearly with the gas velocity. Under equilibrium conditions, $r$ is proportional to the gas velocity, but it reaches a limiting value above a critical velocity when the reaction is governed by the surface reaction rate.

2. Between 44 and 266°C, the formation rate, $r$, of iron carbonyl increases with temperature to a sharp maximum at 245°C in 100% CO. The maximum occurs at 177°C when the CO is mixed with H$_2$, CH$_4$, and CO$_2$. Extrapolation of the rates to higher temperatures indicates that no iron carbonyl should form above 270°C for the mixed gases or above 285°C in carbon monoxide. The data further suggest that $r$ is governed by the reaction rate up to the temperature of the maximum formation rate but that thermodynamic equilibrium is achieved above this temperature. The expression for the equilibrium constant for the reaction

$$1/2\% \text{Mo steel} + \text{CO} \rightleftharpoons \text{Fe(CO)}_5$$

was calculated to be

$$\log K = \frac{9681}{T} - 28.188$$

in 100% CO,

when the pressures are expressed in atmospheres.

3. The equation $r = kP^N_{\text{CO}}$ describes the pressure dependence of the formation of iron carbonyl on $P_{\text{CO}}$. In either gas, $n$ increases moderately with temperature to a probable limiting value of 4.7 under
conditions approaching thermodynamic equilibrium. In contrast, when $r$ is governed by the reaction rate, $n$ is approximately 2.0.

ACKNOWLEDGMENTS

The authors thank W. C. Hawkins for running the experiments described in the manuscript. We are especially pleased with his accuracy and attention to the many details required to conduct these tests under safe and exacting conditions. The authors are also indebted to J. Brynestad for the design of the reaction rate apparatus and the development of the analytical techniques for determining iron and nickel carbonyls.
