The authors would like to thank Dr. V. Protopopescu and Dr. M. Unseren for many insightful discussions during the preparation of this paper.
ABSTRACT

A classical redundancy resolution scheme for an $m$-degree of freedom robot involves the numerical or symbolic computation of the Moore-Penrose pseudo-inverse of the Jacobian matrix, which in turn leads to a least norm solution for the joint velocities (see for example [1]). Since the Jacobian matrix may be ill-conditioned, the computation of the inverse may often turn out to be lengthy and/or inaccurate. In this paper, we propose an alternative method to find this least norm solution. Namely we modify the original underdetermined problem by transforming it into a set of determined new problems. We compute in parallel the solutions of these problems and find their least norm simplex combination. We prove that if the dimension of the task-space is $n$, we need only $(m - n + 1)$ such solutions. We also show that the approach can take into account obstacle avoidance and maximum of manipulability or any other type of analytical criterion. We apply the method to a planar redundant arm.
1. INTRODUCTION

We consider an $m$ degrees of freedom robot. The state it occupies is determined by an articular position vector $q$ of $\mathbb{R}^m$, but usually the specification of a task takes place in another space $\mathbb{R}^n$ called operational space or task-space (for most industrial robots $n = 6$). It is easy to express the operational position $X$ analytically as a function of the articular position $q$:

$$X = F(q); q \in \mathbb{R}^m; X \in \mathbb{R}^n.$$  

However, controlling the kinematics of a robot requires to find the inverse relationship:

$$q = G(X); q \in \mathbb{R}^m; X \in \mathbb{R}^n.$$  

In most of the cases, it is impossible to obtain this relationship analytically and globally. Usually, the problem is solved by linearizing the operator $F(q)$ in the neighborhood of the point $q$. A small variation $\Delta X$, called task-vector, of the end-effector position is expressed in the operational space (or task space) as:

$$\Delta X = J(q)\Delta q; \Delta q \in \mathbb{R}^m; \Delta X \in \mathbb{R}^n.$$  \hspace{1cm} (1)

where $J$ is the $(n \times m)$ Jacobian matrix and $\Delta q$ is the corresponding small variation of the articular position. We assume that $J$ has rank $n$; for a fixed $q$ and for a specified $\Delta X$, the set of solutions is an affine space of dimension $m - n$, which we shall denote by $\mathcal{E}$.

Controlling the kinematics of the robot is equivalent to solve periodically this system, i.e. to determine a suitable control vector $\Delta q$ as a function of $\Delta X$, the task-vector. In most applications, the operational space has a dimension $n = 6$. In the case of a non-redundant arm, $m = 6$ and provided the Jacobian matrix $J(q)$ is invertible ($q$ is not a singular position), the solution $\Delta q$ is given by:

$$\Delta q = J^{-1}(q)\Delta X; \Delta X \in \mathbb{R}^6; \Delta q \in \mathbb{R}^6; q \in \mathbb{R}^6.$$  \hspace{1cm} (2)

In the case of redundant arms ($m > n = 6$), the Jacobian matrix is not square and cannot be inverted. One method consists of finding the $\Delta q$ of least norm that verifies Eq. (1). This leads naturally to the introduction of a pseudo-inverse of $J$, namely $J^T(JJT)^{-1}$. To avoid the computation of the pseudo-inverse, algorithms work with square sub-matrices of the Jacobian matrix to compute the solutions, but these algorithms are tailored for 7-d.o.f. manipulators ($m = 7$) and it is not possible to generalize them for robot with more d.o.f. As an alternative, we propose to extract numerically well-behaved square sub-matrices of $J$, obtain their solutions, and find their least norm simplex combination. One advantage of this approach is its generality to $m$-d.o.f. arms and its inherent parallel structure.
2. THE PSEUDO-INVERSE ALGORITHM

To solve \( \min \frac{1}{2} \| \Delta q \|^2 \) subject to the constraint (1), we introduce the Lagrangian:

\[
L(\Delta q, \mu) = \frac{1}{2} \| \Delta q \|^2 + < \mu, J\Delta q - \Delta X >
\]

and solve the necessary optimality conditions:

\[\Delta q + J^T \mu = 0 \quad (3)\]
\[J\Delta q - \Delta X = 0. \quad (4)\]

Multiplying Eq. (3) by \( J \) and using Eq. (4), we get

\[\Delta X + JJ^T \mu = 0.\]

If we assume that \( J(q) \) has a maximal rank (\( q \) is not a singular position), i.e. \( n \), then we can invert \( JJ^T \):

\[\mu = -(JJ^T)^{-1} \Delta X.\]

Substituting this value of \( \mu \) in Eq. (3) gives:

\[\Delta q^* = J^T(JJ^T)^{-1} \Delta X \quad (5)\]

where \( J^T(JJ^T)^{-1} \) is the Moore-Penrose pseudo-inverse of the Jacobian matrix [2]. Nevertheless, the implementation of this algorithm very often fails because the numerical computation of the pseudo-inverse is often very ill conditioned (small determinants, large differences between various elements, etc.) [3]. Furthermore, the determination of the pseudo-inverse using the SVD (singular value decomposition) technique is too slow for a real-time implementation. Other difficulties in resolving the redundancy using the SVD method to calculate the pseudo-inverse of \( J(q) \) are described in [4].
3. THE PROPOSED ALGORITHM

To avoid the computation of the Moore-Penrose pseudo-inverse,[5] applies Gradient Projection Method to a 7-d.o.f. arm and the form of the solution is:

\[ \Delta q = \Delta q_p + k \Delta q_h; \Delta q \in R^7; \Delta q_p \in R^7; \Delta q_h \in R^7; k \in R. \]

Here \( \Delta q_p \) is a particular solution of Eq. (1) and \( \Delta q_h \) is the solution of the homogeneous equation:

\[ \bar{0} = J(q)\Delta q_h; \Delta q_h \in R^7; \bar{0} \in R^6. \]

This algorithm is computationally efficient and was successfully implemented. However, concerning optimality, no proof was provided that the result is the least norm solution. Moreover, it is not possible to guarantee an upper bound of the computation delay as the algorithm includes \( \text{repeat...until} \) statements in the flow control. Besides, no study was carried out to study efficient implementation of the Gradient Projection Method applied to an arbitrary number \( m \) of degrees of freedom.

In [6], an interesting combinatorial approach to Inverse Kinematics is proposed. The idea is to extract all the \( s \) possible \( n \times n \) submatrices of the Jacobian matrix, invert them, and solve in parallel the associated linear systems analogous to Eq. (1). Then, among the \( s \) solutions, one picks the one with the least norm. The intuitive interpretation is that it is possible to physically block enough joints to compensate the underspecification of the problem. In that case the time boundedness of the computation is guaranteed. However, the solution obtained is not necessarily the least norm one, since the best solution produced by this scheme always includes the blocking of one of the joints.

We suggest a similar technique, based on the linear properties of the coordinate transformation in the neighborhood of the point \( q \) expressed by the Jacobian matrix \( J \) and its \( s = C^n_m \) submatrices \( J_1, J_2, \ldots, J_k, \ldots, J_s \) of dimension \( n \times n \). If each \( J_k \) is assumed invertible, it is possible to obtain \( n \)-dimensional vectors \( \Delta q_k \) such that:

\[ \Delta q_k = J_k^{-1} \Delta X, (\Delta q_k \in R^n, k \in \{1, \ldots, s\}) \quad (6) \]

Without changing their names, we can rewrite these vectors \( \Delta q_k \) as \( m \)-dimensional vectors in the articular space, setting the \( (m - n) \) complementary components to 0. Specifically, if the submatrice \( J_k \) is formed by blocking columns \( i_1, i_2, \ldots, i_{m-n} \) in \( J(q) \), then the components of positions \( i_1, i_2, \ldots, i_{m-n} \) are set to zero in the corresponding \( m \)-dimensional vector \( \Delta q_k \). Let us consider a maximal set of independent vectors \( \Delta q_k, k = 1, \ldots, p \). We now introduce \( E \), the affine space of dimension \( \text{dim}(E) = p - 1 \) spanned by the family \( \{\Delta q_1, \ldots, \Delta q_p\} \):

\[ E = \left\{ \Delta Q \in R^m \mid \Delta Q(t_1, \ldots, t_p) = t_1 \Delta q_1 + \cdots + t_p \Delta q_p; \sum_{k=1}^{p} t_k = 1 \right\} \quad (7) \]

Since the \( m \)-dimensional vectors \( \Delta q_k \) are solution of the original problem, \( E \) is a subspace of the affine space \( E \) (of dimension \( m - n \)) defined by the solutions of Eq. (1) and thus \( p - 1 \leq m - n \). Now:
6 THE PROPOSED ALGORITHM

- If $p - 1 < m - n$, the optimal least norm solution of Eq. (1) may not belong to $E$, therefore the algorithm does not necessarily give it;
- If $p - 1 = m - n$, then $E$ coincides with $E$ the set of solutions of Eq. (1) and the optimal solution necessarily belongs to $E$.

We can thus find the least norm vector using the parameterization (7). Specifically, we have to find:

$$
\min \frac{1}{2} \|t_1 \Delta q_1 + \cdots + t_p \Delta q_p\|^2
$$

subject to the constraint $\sum_{k=1}^{p} t_k = 1$. The corresponding Lagrangian is:

$$
L(t_k, \beta) = \frac{1}{2} \|t_1 \Delta q_1 + \cdots + t_p \Delta q_p\|^2 + \beta(\sum_{k=1}^{p} t_k - 1)
$$

from which we derive the necessary optimality conditions:

$$
\sum_{k=1}^{p} t_k = 1
$$

$$(\forall k \in \{1, \ldots, p\})(t_1 < \Delta q_1, \Delta q_k > + \cdots + t_p < \Delta q_p, \Delta q_k > + \beta = 0).$$

We denote by $G$ the Gramian matrix of the vectors $\{\Delta q_1, \ldots, \Delta q_p\}$ for which $g(i,j) = \langle \Delta q_i, \Delta q_j \rangle$. We call $t = (t_1, \ldots, t_p)^T$ and $e$ the $p$-dimensional vector $(1,1,\ldots,1,1)^T$. Then Eqs. (9) and (10) can be expressed in the simpler form

$$
e^T t = 1, \quad Gt + \beta e = 0.
$$

Since $G$ is invertible ($\{\Delta q_1, \ldots, \Delta q_p\}$ are independent), we get easily

$$
t^* = \frac{G^{-1}e}{e^T G^{-1}e}.
$$

The least norm $\Delta Q$ is thus

$$
\Delta Q = \sum_{k=1}^{p} t_k^* \Delta q_k.
$$

In conclusion, $(m - n + 1)$ independent solutions of Eq. (1) suffice to compute the least norm $\Delta Q$. For instance, in the case of the 7-d.o.f. spatial serial link arm, only two 6-dimensional vectors are required to control the robot. Moreover, the advantage of this algorithm over the Pseudo-Inverse Algorithm is that the square submatrices can be tested for ill-conditioning or singularity. Since, for a $m$-d.o.f. redundant robot, $\binom{n}{m} > m - n$, one has a very good chance to find $m - n + 1$ well-conditioned submatrices and use those to determine the solution space. In the following, we illustrate the method on a 4-d.o.f. planar arm, using the symbolic manipulation environment Mathematica [7] on Macintosh II.
4. APPLICATION TO A 4-D.O.F. PLANAR ARM

Let us apply the algorithm to the arm illustrated in Fig. 1. We specify the translational position of the robot tip at point $X_E$, but do not specify orientation of the outermost link and end effector. Since we have 4 degrees of freedom and the task space is 2-dimensional, we need $(4 - 2 + 1) = 3$ solutions $\Delta q_k$. The Cartesian displacement is denoted $\Delta X = (\Delta x, \Delta y)$. Among the $4 \times 2$ submatrices $J_{rs}$ that can be extracted from $J$ by selecting successive columns (with obvious notation $J_{12}$ corresponds to blocking joints 3 and 4), we select the three having the largest determinant (for a reason of sensitivity to noise) and compute the three corresponding $\Delta q_{rs}$.

$$\Delta q_{rs} = (J_{rs}^{-1}) \Delta X.$$  

We then compute the associated Gramian matrix $G$, get $t^*$ from Eq. (12), and $\Delta q$ from Eq. (13). Figure 2 illustrates the motion of the arm when the end-effector follows a circular trajectory. Fifty elementary displacements $\Delta X$ are used to describe the circle. We refer the reader who is familiar with Mathematica to the listing of the program given in Appendix A.

![Four-degree-of-freedom planar arm](image)

**Fig. 1.** Four-degree-of-freedom planar arm.

This simulation was performed by a classical sequential program. However, it is possible to improve the time performance of this inversion by parallelizing data processings. Let us recall that the robot has $m$ degrees of freedom and that the task has $n$ degrees of freedom. The first step of the algorithm is to select the $p = (m - n + 1)$ matrices that will determine the solution. We extract in parallel $m \times n$ matrices $J_k$, compute their determinants, inverses, and associated vectors $\Delta q_k$ (for a more efficient on-line implementation, the explicit inversion of $J_k$ can...
be avoided by using a Gaussian elimination with partial pivoting. We keep the vectors $\Delta q_k$ corresponding to the largest determinants. Then the computation of the Gramian matrix $G$ is also made in parallel. The remaining computations are the inversion of $G$ (which is symmetric and well-behaved) and the computation of the vectors $t^*(t_1, \ldots, t_P)$ and $\Delta q$.

Fig. 2. Plotting of the arm and the end effector obtained by simulation.
5. GENERALIZATION OF THE ALGORITHM TO OTHER CRITERIA

In the preceding section, we have shown that it is possible to resolve the redundancy without explicitly computing the pseudo-inverse of the Jacobian matrix. Our approach was to minimize a criterion over the affine space defined by Eq. (1) that we parameterized using \( p \) vector solutions. Suppose that we now also want to minimize a potential function in order to avoid obstacles, (like in Khatib et al. [8], or to maximize a manipulability index, as defined in Yoshikawa [9]. Let us denote by \( \mathcal{P}(\Delta q) \) such a criterion, expressed as a function of \( \Delta q(t_1, \ldots, t_p) \), the elementary displacement in the articular space. Then, we only need to replace the problem in Eq. (8) by the new problem

\[
\min \frac{1}{2} \| t_1 \Delta q_1 + t_2 \Delta q_2 + \cdots + t_p \Delta q_p \|^2 + \lambda \mathcal{P}(\Delta q(t_1, \ldots, t_p))
\]  

(14)

where \( \lambda \) is a weight factor, and the real parameters \( t_k \) are still subject to the constraint \( \sum_{k=1}^{p} t_k = 1 \). In this case, one must note that, in general, no closed-form solution like Eq. (13) will be found. This is the subject of our future work.
6. CONCLUSION

In this paper, we have presented an alternative scheme to resolve the kinematics of a redundant robot. This scheme can be efficiently parallelized and contains well-behaved matrices for numerical processing with a computer. The future work that we envision is an extensive comparison of this method with current approaches when the task function [10] of the robot includes several other criteria as well. In particular, the application of decomposition/coordination schemes (see for example Cohen [11] and references therein) should enable us to preserve the parallel structure even with non-additive criteria such as potential and manipulability functions.
